Abstract. Heramza K, Barour C, Djbourabi A, Khati W, Boullag C. 2021. Environmental parameters and diversity of diatoms in the Ain Dalia dam, Northeast of Algeria. Biodiversitas 22: 3633-3644. Diatoms have long been used as biological indicators of the quality of aquatic environments due to their important capacity to respond to environmental change. As this flora has been very little studied in Algeria, the present study aimed to monitor the Spatio-temporal dynamics of diatoms at the Ain Dalia dam (north-eastern of Algeria) and determine the main abiotic factors contributing to these variations from June 2017 to May 2018 in four selected stations. Our results showed that the waters of Ain Dalia dam waters vary from moderately (St1 and St3) to significantly polluted (St2 and St4). They host the community of planktonic diatom flora composed of 72 species. The interspecific biodiversity was marked in summer and autumn (57 and 56 species respectively) and in the St4 station (52 species). In terms of abundance, more than 40% of the overall density was found in the St4 station and the fall period. Among the dominant genera, Cyclotella, Thalassiosira, Synedra and Navicula are found in moderately polluted waters, while Nitzschia, Melosira and Surirella in significantly polluted waters. Some environmental parameters, including nutrients (PO4,3− and NO3−), SM, temperature, dissolved oxygen, and pH played a key role in the functioning and evolution of this lake. Hence, these parameters demonstrated important fluctuations during our study and influenced directly the diatom distribution. These results showed that diatom assemblages are influenced by anthropogenic disturbances, and can be used as indicators of environmental quality.

Keywords: Bacillariophyceae, biodiversity, freshwater, physicochemical parameters, water quality

INTRODUCTION

Diatom communities respond directly to physical and chemical changes in the environment. Previous studies conducted on the diatom ecology have shown that the community structure depends on many factors, including organic matter (Sládeček 1986), pH (Renberg and Hellberg 1982; Zampella et al. 2007), nutrients (Kelly 1998; Pan et al. 1996), depth and water temperature (Afonina et al. 2020). Furthermore, a large diversity of ecological preferences between species results in structural changes in the diatom community. Also, the relatively short generation time makes diatoms rapidly respond to environmental changes, and consequently provide an early signal in the event of pollution (McCormick and Stevenson 1998).

The composition and distribution of aquatic organisms are usually determined by the spatio-temporal dynamics of the environment. In the biotopes different in hydrological and physico-chemical parameters, the plankton communities differ in species composition and abundance (Skála 2015; Voutilainen et al. 2016). Diatoms are used to track the effect of climate (Ruhland et al. 2008) and nutrient enrichment (Hall and Smol 2010). They also often dominate the algal communities in many freshwater systems. Although the ecological importance of diatoms, they were rarely studied in Algeria. These studies were mainly conducted on the continental diatoms of Algeria Baudrimont (1973), and the assemblages of the diatoms in Algerian wadi (Ounissi and Frehi 1999; Al-Asadi et al. 2006; Lange-Bertalot et al. 2009; Chaib et al. 2011; Chaib and Tison-Rosebery 2012; Hamaidi-Chergui et al. 2013; Djbourabi et al. 2014; Nehar et al. 2014; Nehar 2016; Draredja 2019; Draredja et al. 2019a,b; Chabaca et al. 2020).

In Algeria, the only study that investigated the ecology of lentic diatoms was undertaken by El Haouati et al. (2015) in Lake Reghaia. In this perspective and to contribute modestly to the enrichment of knowledge on the ecology of the freshwater diatoms, this work aimed to study the environmental factors influencing the diatom flora of Ain Dalia reservoir (North-East of Algeria).

Our study is devoted to the diatoms and their spatial and temporal distribution in four selected stations from June 2017 to May 2018. In addition, we identified the diatoms communities and determined the abiotic factors driving their distribution.
MATERIALS AND METHODS

Study area

The Ain Dalia dam is located in the extreme north-eastern part of Algeria, 10 km south of Souk-Ahras city (Table 1). The dam water reservoir has an area of 217 km² and a total capacity of 82 million m³ (Figure 1). According to the National Agency of Dams and Transfer, the surface water resources are provided mainly by the Wadi (River) of Medjerda which flows from Khemissa region to the Tunisian territory crossing Souk-Ahras city on a length of 113.6 km (NADT 2013).

Physicochemical measurements, sampling, and treatment of phytoplankton

A sampling of phytoplankton and measurements of some physicochemical parameters were performed monthly from June 2017 to May 2018 in four selected stations. The geographical position and the characteristics of sampling stations are displayed in Table 1.

Physicochemical measurements (temperature (T, °C), dissolved oxygen (O₂, mg.L⁻¹), pH) were carried out in situ using a multi-parameter analyzer (Consort C561). While nutrients (nitrite, NO₂⁻ and orthophosphate, PO₄³⁻) were assessed using the spectrophotometers method (Aminot and Chaussépie 1983). To measure the concentration of suspended matter (SM), a heat-treated (450 °C, 30 min) glass fiber filters of 0.45 μm nominal porosity (47 mm diameter, Whatman GF/CTM, Germany) were pre-weighed and then used for the filtration of the surface water samples. After filtration, the filters were dried at 70 °C for 48 h. The SM concentration was determined from the difference between the weight of the filter before and after filtration (Aminot and Chaussépie 1983).

Figure 1. The geographical location of the Ain El-Dalia Dam, Northeast of Algeria and the distribution of the stations. (St1: station 1, St2: station 2, St3: station 3, St4: station 4)
Phytoplankton sampling was performed by filtering the surface water samples using plankton net of 20 µm of mesh, and collected samples were fixed immediately with formaldehyde (concentration 10%). The identification of Diatoms is based on the observation of morpho-anatomical characteristics using a light microscope (Carl Zeiss, Axiosstar Plus Microscope) and according to appropriate taxonomic literature like Bourrelly (1985); Loir (2004); Bey and Ector (2013); Peeter and Ector (2017, 2018), whose the taxonomic database “Algae base” was used to standardize the scientific names of diatom taxa. The cell counting was carried out using Nageotte cell counting chamber (Brient et al. 2001). The Diatoms’ fauna diversity structure was assessed by calculating the Shannon-Weaver diversity index H’ (Shannon and Weaver 1949), the Simpson’s diversity index (D) (Simpson 1949), and the Pielou’s evenness index J’ (Pielou 1975). Additionally, the dominance of the major taxa (D%) was determined according to Ngansoumana (2006).

Statistical analyses
All our statistical analyses were performed using R, version 4.0.1 (R Core Team 2020). The Shapiro-Wilk test tested the normality of all variables data. Median differences among seasons and stations were tested by the rank-based nonparametric test of Kruskal Wallis followed by posthoc pairwise comparisons using Dunn’s test with Holm’s P-value adjustment by using the 'Dunn test' package (Dinno 2017). The spatiotemporal variation of our tested biotic and abiotic variables is plotted through many boxplots graphs by using the ‘ggplot2’ package (Wickham 2016); different lowercase letters indicate a significant difference between the levels of the studied factors. Results are given as means ± SD (standard deviation). All the statistical analyses were realized at α= 0.05 as a significance level.

In addition, the relationships between physicochemical and biological parameters were analyzed by the non-parametric Spearman correlation using ‘ggcorrplot’ (Kassambara 2019) and ‘Hmisc’ (Harrell et al. 2020) packages. We carried out also the principal component analysis (PCA) using the ‘FactoMineR’ (Husson et al. 2020) and ‘facto extra’ (Kassambara and Mundt 2020) packages on standardized data to characterize the spatiotemporal variation of the measured biotic and abiotic variables in Aïn Dalia dam.

RESULTS AND DISCUSSION

Composition of diatom communities
The inventory of diatoms resulted of a total of 72 species represented by 17 centric and 55 pennate belonging to 31 genera and 21 families. Six families are the richest in species (S: specific richness ≥ 4): Melosiraceae (8 species), Naviculaceae (15 species), Cymbellaceae (6 species), Fragilariaceae (7 species), Bacillariaceae (8 species), and Surirellaceae (5 species). However, the species richness in the other families' does not exceed 3 species (S< 4): Asterolampgaceae (1 species), Biddulphiaceae (2 species), Heliolpeltaceae (2 species), Stephanodiscaceae (2 species), Thalassiosiraceae (4 species), Achnanthes (2 species), Catenuelaceae (2 species), Rhoicospheniaceae (2 species), Licmophoraceae (1 species), Stauroneidaceae (1 species), Entomoneidaceae (2 species), Rhopalodiaceae (1 species), Amphipleuraceae (1 species), Pinnulariaceae (1 species), Eunotiaceae (1 species) (Table 2).

The dominance index (D) estimation of the 31 identified genera, revealed the dominance of Cyclotella (D= 18.97%), Melosira (D = 13.30%), Thalassiosira (D= 13.07%), Nitzschia (D= 8.51%), Navicula (D= 8.14%) Surerilla (D= 5.38%) and Synedra (D= 5.34%). The other genera are secondary taxa (D>5%) (Table 2).

Note: D: Dominant (D ≥ 5%), S: Secondary (D<5%) (Ngansoumana 2006)
Seasonal and spatial distribution of diatoms

In terms of proportions in relation to the overall density of the diatoms collected, the diatoms show seasonal densities that evolve in decreasing order according to autumn (43%) ≥ Winter (25%) ≥ Summer (18%) ≥ Spring (14%). Furthermore, the highest proportions are found in St4 (44%) compared to 20%, 19%, and 17% respectively in St3, St2, and St1 (Figure 2).

Seasonal distribution of dominant genera

Among the dominant genera, those that predominate in terms of abundance are Melosira, Cyclotella and Nitzschia in autumn (72% of seasonal density), Thalassiosira, Cyclotella and Synedra in spring (80%), Navicula, Nitzschia and Thalassiosira in summer (66%) and Cyclotella, Thalassiosira and Melosira in winter (77%) (Figure 3).

Spatial distribution of dominant genera

Among the 7 dominant genera, we note, in stations St1, St2 and St3, the predominance of Cyclotella and Thalassiosira, which together account for 64%, 58% and 57% respectively; in station St4, the predominant genera are Melosira and Surirella (35 and 18% respectively) (Figure 4).

Ecological indices

Diatoms species, diversity and evenness indices per season and station are shown in Table 3. The maximum richness was observed in autumn (S = 57 species, H’=3, D=0.926, E=0.742) and summer, (S= 56 species, H’=2.999, D=0.926, E=0.742). Regarding spatial specific richness, the highest values of ecological indices are recorded in station St4 (S=52 species; H’=3 and D=0.926; E>0.761) (Table 3).

Statistical analyses

Physicochemical characterization of Ain Dalia Dam’s water

The spatial and temporal variations of the physicochemical parameters of the waters of Ain Dalia are shown in Table 4.
The difference in T between stations is only 3°C; however, the difference is about 14°C between winter (10.73°C) and summer (24.86°C), with intermediate values in autumn and spring. The pH of the Dam’s water is alkaline (≥ 7.5); high values are recorded in spring (7.99) and at the St3 (7.89) and low values (7.56) in winter and at the St2. The O₂ saturation levels ranged from 34 to 73%; minimums (close to 34.5%) are recorded in summer and in St2 and maximums in winter (66.46%) and in St1 (73.71%). The lowest SM concentrations are noted at St1 and St3 (25 and 53 g.L⁻¹, respectively) and the highest at St2 and St4 (139 and 158 g.L⁻¹, respectively). Excepting winter, when SM levels reached 160 g.L⁻¹, the values in the other seasons fluctuated between 61 and 79 g.L⁻¹.

Furthermore, in winter and at St1 the orthophosphate levels showed values that are less than 0.05 mg.L⁻¹, while values that are greater than 0.2 mg.L⁻¹ are observed in summer and at St4; values between 0.1 and 0.2 mg.L⁻¹ are found in autumn and spring and at St2 and St3. Moreover, nitrite values ranged from 0.02 to 0.23 mg.L⁻¹; values that are less than 0.1 mg.L⁻¹ were found at St1 and in winter and values greater than 0.20 mg.L⁻¹ were found at St2 and St4 and in summer; whereas the intermediate values are recorded in spring and autumn at St3.

The comparison between stations by using the non-parametric Kruskal Wallis test revealed significant differences (p< 0.05) for the following variables: Melosira (MEL), Surirella (SUR), dissolved oxygen (O₂), suspended matter (SM), and nutrients (NO₂ and PO₃⁻). Concerning the season factor, the Kruskal Wallis test revealed also significant differences for Navicula (NAV) and Nitzschia (NIT) loads as well as for orthophosphates (PO₃⁻), temperature (T), and dissolved oxygen (O₂). In addition, the post hoc pairwise comparisons of the Dunn’s test are presented by boxplots shown in Figure 5 for season factor and Figure 6 for station factor.

**Correlation analysis between environmental parameters and Diatoms’ density**

The non-parametric spearman correlation analysis is presented in Figure 7 and showed, in the one hand, a significant positive correlation (p ≥ 0.5) between Navicula and T (r = +0.67), Synedra and pH (r = +0.53), Navicula and Nitzschia (r = +0.54), Thalassiosira and SM (r = +0.57) and Thalassiosira and NO₂ (r = +0.56), and on the other hand, a significant negative correlation between Synedra and Nitzschia (r = -0.55), Synedra and Navicula (r = 0.65), Synedra and T (r = -0.50), Nitzschia and pH (r = -0.57), Nitzschia and O₂ (r = 0.62), Navicula and pH (r = -0.60), Thalassiosira and O₂ (r = -0.53).

**Spatiotemporal variation analysis of the physicochemical and the Diatoms’ distribution: Principal component analysis (PCA)**

Generally, the PCA results show the spatiotemporal variation of some biotic and abiotic parameters in Ain Dalia Dam; show a clear structuring for sampling stations and season. In a summarized way, the PCA resulted in two relevant components that accounted for 72.21% of the spatiotemporal data variance (total inertia). This percentage is relatively high and thus the first plane well represents the Spatiotemporal data variability and the description will stand to these two first axes.

On the one hand, the first PCA axis alone explains 43% of the total dataset inertia and shows positive correlation with: NO₂ (r = +0.79, cos²=0.63), PO₃⁻ (r = +0.71, cos²=0.51) and Nitzschia (r = +0.55, cos²=0.30); but it displayed a negative correlation with O₂ (r = -0.92, cos² = 0.85) and pH (r=-0.54, cos² = 0.29) (Figure 8.C).
Figure 5. Seasonal variations in physicochemical and biological parameters in the Ain Dalia Dam (n= 48). Different letters indicate a significant difference among levels of variables (p< 0.05). Central box limits show the interquartile range (IQR) with the first (lower box bound) and third (upper box bound) quartiles. Outliers (values outside IQR limits ± 1.58 times IQR) are indicated by small black points.

Figure 6. Spatial variations in physicochemical and biological parameters in the Ain Dalia Dam (n= 48). Different letters indicate a significant difference among levels of variables (p< 0.05). Central box limits show the interquartile range (IQR) with the first (lower box bound) and third (upper box bound) quartiles. Outliers (values outside IQR limits ± 1.58 times IQR) are indicated by small black points.
This axis explained clearly a distinction between our four sampling stations: St2 and St4 are characterized by fairly high levels of nitrites, and orthophosphates as well the density of Nitzschia genus; while the St1 and the St3 are richly oxygenated with high pH values and with a dominance of both Cyclotella and Synedra genera (Figures 8.A-B). On the other hand, the second PCA axis explains 29.20% of the total dataset inertia; it is positively correlated with T ($r = +0.76$, $cos^2 = 0.58$) but negatively correlated with SM ($r = -0.83$, $cos^2 = 0.69$). This axis reveals a clear seasonal structure, which allows us to distinguish the hottest months from the coldest ones, it opposes the summer season to the winter season with two overlapping seasons (spring and autumn). From Figure 8.B-C, we can conclude that the high levels of suspended matter (SM) were registered in the winter season with a dominance of both Synedra and Thalassiosira genera, in opposition to Navicula genus which could appear in the summer season.

Discussion

Environmental parameters

The pH of the waters of Ain Dalia dam is alkaline (7.5-7.9). The highest values of the pH were observed in St1 and St3 where dissolved oxygen levels are highest; A positive correlation is noted between pH and dissolved oxygen ($p<0.05$). Our data were in accordance with those reported by Chabaca et al. (2020) at the Lake Oubeira, by Draredje et al. (2019) at the Lake Melleh, by Ayad and Kahoul (2016) at the well water in the region of El-Harrouch, by Kahoul and Touhami (2014) on drinking water of the city of Annaba and by Manamani 2007; Agouni 2013 at the Ain El-Dalia dam, for which they report pH values between 6 and 9. Indeed, this alkalinity could be due to the increase in diatom communities (Seyni 2006), by an increase in oxygen in the water and by the consumption of CO2 through photosynthesis (Stum and Morgan, 1991; Martin 2004).

The water of stations St4 and St2 was low in oxygen. The oxygen uptake could explain these low values by the bacteria (Dandelot et al. 2005), which was favored by the increase of urban and industrial wastewaters containing a great quantity of organic matter (Arrignon 1998). A significant negative correlation between dissolved oxygen and SM and PO$_4^{3-}$ ($p<0.05$) and a highly significant correlation between dissolved oxygen and NO$_2$ ($p<0.001$) were noted.

Both Stations St4 and St2 displayed a high level of pollution in contrast to the rest of the stations (St1 and St3) which exhibited a moderate level of pollution. The St4 and St2 stations have the highest SM, NO$_2$ and PO$_4^{3-}$ levels because their water comes from municipal and treatment plant discharges. These data agree with those reported from the Oued of Madjerda by Nait Merzoug (2012), who confirmed an adverse impact on the physicochemical characteristics. This implies that the water of this river has a major pollution problem.

According to Savary (2003), the fluctuations of the suspended solids indicated a certain irregularity both at spatial and temporal levels, according to the season, rainfall, and discharges. The evolution of the nitrogen contents showed a temporal difference. The low values were dependent on important nitrification (Abba et al. 2008) and a strong absorption (Issola et al. 2008).
Taking into account the average annual dissolved oxygen, nitrate, and phosphate contents recorded in the 4 stations, we can consider the waters of stations St1 and St3 as class II (presenting moderate pollution and therefore of mean quality) and those of stations St2 and St4 as class III (presenting significant pollution and therefore of very low quality). In terms of SM content, the dam waters would be excessively polluted and would thus be part of class IV (ANRH. 2000).

**Composition of diatom communities**

The present study carried out on diatomic settlement in Ain Dalia dam promotes inventing 72 species distributed in 31 genera. These findings, particularly those of some taxa carried out in El-Kula region (north-east Algeria) were previously reported, including those in Chelif river (Al-Asadi et al. 2006), the black Lake (Amri 2008), Kebir river (Chaib et al. 2011), Oubeira and El Malah Lake (DRAREDJIA 2007; EL-HAOUATI et al. 2015; DRAREDJIA 2019; DRAREDJIA et al. 2019a, b), Oubeira Lake (Djbourabbi et al. 2014 2017; Chabaca et al. 2020). Furthermore, some other data regarding these species were reported from previous studies carried out in Algeria; in the Gulf of Annaba (north-eastern of Algeria) (Ounissi and Frehi 1999), in Chiffa Blida river (Hamaïdi-Chergui et al. 2013), in Sidi-Yacoub dam (Houari 2009) and in some of watercourse of Oranie (Nehar et al. 2015; Nehar 2016).

Diversity is a crucial ecological subject, generally perceived as the best indicator of the ecosystem health status (Magurran 1988). In this study, the maximum richness was observed in autumn (S= 57 species, H'=3, D=0.926, E=0.742) and summer, (S= 56 species, H'=2.999, D=0.926, E=0.742). Regarding spatial specific richness, the highest values of ecological indices are recorded in station St4 (S=52 species; H'=3 and D=0.9260; E>076). In terms of proportions in relation to the overall density of the diatoms collected in Ain Dalia dam, the diatoms show seasonal densities that evolve in decreasing order according to autumn (43%) ≥ Winter (25%) ≥ Summer (18%) ≥ Spring (14%). The dominance index (DI) estimation of the 31 identified genera from waters of Ain Dalia dam, revealed the dominance of *Cylotella* (D = 18.97%), *Melosira* (D = 13.30%), *Thalassiosira* (D = 13.07%), *Nitzschia* (D = 8.51%), *Navicula* (D = 8.14%) *Surirella* (D = 5.38%) and *Synestra* (D = 5.34%).

However, the study performed by Nehar (2016) has revealed that the results of settlement structure from El-Hammam and Chelif rivers (North-east Algeria) provided generally, low mean values. On the other hand, Drariedja et al. (2019a) reported that the diversity of populations of diatoms in the Mellah is up to 4.56 bits.cell^{-1} and with a of regularity of 0.98, and thus suggesting populations of structured diatoms for a single period of the year (winter and late spring). However, the rest of the cycle is characterized by unstable species composition. Chabaca et al. (2020) in Oubeira Lake showed that the genera *Cymbella* and *Navicula* dominated the two stations of Oubeira Lake.

In the Reghaia dam lake, El Haouati et al. (2015) report the presence of 24 species belonging to 13 genera; this
diversity increased during the spring and autumn periods. In Reghaia Lake, the abundance of taxa study showed that the genus *Cyclotella* occupied an important place in the diatom community, with more than 50% of the diatoms present in winter and summer; during the spring and autumn periods, they noted the dominance of *Stephanodiscus* and *Navicula*. In the Beni Haroun dam, the number of species is 14 for 9 genera; in this water body, the most representative genera of the group of Bacillariophyceae are *Cyclotella, Navicula* and *Nitzchia* (Kherief Nacereddine et al. 2018). Of all the species described in the three water bodies, only the species *Stephanodiscus* sp. is found exclusively in Reghaia. However, we note that the genus *Cyclotella* genus is dominant in Ain Dalia as well as in Reghaia and Beni Haroun. According to Airill et al. (2016), in shallow nutrient-rich turbid water diatoms like *Cyclotella, Stephanodiscus, Asterionella, Diatoma, Fragilaria, Navicula, Nitzchia, Melosira* and *Synebra* exist in higher density. Members of Bacillariophyceae like *Navicula, Nitzchia,* and *Synebra* species can tolerate pollution and be used as sewage pollution indicators (Shekhar et al. 2008).

According to Häkansson (2002), the genus *Cyclotella* often dominates species assemblages in paleolimnology, particularly in the circum Mediterranean region, and can cause difficulties or loss of information in paleoenvironmental reconstructions due to the ongoing taxonomic uncertainty in this group. In the waters of the Ain Dalia dam, the genus *Cyclotella* shows the highest proportions in stations St1 and St3 (respectively 58%, 20% and 32% of the overall seasonal abundance) and therefore seems to be able to accommodate strong variations in oxygen saturation rates (73%, 35% and 55% respectively in St1, St2 and St3) and T° between 17 and 19°C. Cremer and Wagner (2003) suggested that the *Cyclotella ocellata* complex must comprise several different species or ecological groups, exhibiting contrasting ecological preferences for nutrient status, which may relate to the biogeographic region in which they grow. It also occurs in slow-flowing rivers as plankton or periphyton (Krammer and Lange-Bertalot 1991; Ehrlich 1995; Houk et al. 2010). According to Loudiki (1990), this genus presents a recognizable heliophilous character and it develops in an optimal way when the temperature is around 20°C. Species of the genus *Cyclotella* represent an important component of the diatom community of eutrophic lakes (Schelegel and Scheffler 1999) and they were already reported in the diatom community of eutrophic lakes (Schelegel and Cremer 2008).

The genus *Nitzchia*’s relatively strong presence is noted in warm periods (autumn and summer) and in the St4 station where it seems to seek waters with relatively high SM, NO3 and PO4 contents and low dissolved oxygen (r = -0.62).

The species of the genus *Navicula* are present in all the stations in proportions varying from 7 to 15%; the genus *Navicula* shows preferences for the summer period when high temperatures are favorable (r = 0.67) and for moderately polluted environments such as stations St1 and St3 where it records scores of the order of 11 and 15% respectively.

The genus *Synebra* shows its highest score in the St3 plant and especially in spring; the latter seems to prefer the alkaline waters of the St3 station (r = 0.53) and spring when the pH is quite high (r = 0.53) and temperatures are quite low (r = -0.50).

The genus *Surirella* shows its highest score (18%) in the St4 station, considered to be the most polluted area of the water body; The latter shows the highest concentrations of MS, NO3 and PO4 that *Surirella* is looking for to develop, although the results of the Spearman test do not reveal the existence of significant correlations between all these parameters. Besides, *Surirella* species are sometimes common in acid waters in high-altitude lakes and peats and they develop in waters moderately rich in organic matter, but they are more common in waters with high temperatures, alkaline pH values, and relatively high conductivity (Sala et al. 2013).

The results of Hamaidi-Chergui et al. (2013) showed that the algal flora (diatoms) found in the Chiffa water river was dominated by the genera *Synebra* and *Melosira*. In the same context, the published work of Sidi Yakoub Bezzeghoud et al. (2014), in the seminar of ADLAF, proved the presence of 66 species and a variety of 23 genera in Rhiou river and El-Malah river (basin of low Chelf and basin of Tafna), in which the species *Pénapatophydidées* are dominating with 64 species against 2 species of *Centriphydées*. Similarly, the authors have shown the dominance of genus *Diatoma* with a rate of 42.37% as compared with the genus *Nitzchia* (17.5%) found at the Rhiou river, since the genera *Nitzchia et Navicula* are predominant in Malah river, along with rates of 63.87% and 18.5% respectively. However, the study of Draredjia et al. (2019a), in the Melleh lagoon, indicates that the dominant genus is *Nitzchia*. The study of Chabaca et al. (2020), in the Oubeira lake, indicated that the genera *Cyclotella* and *Nitzchia* dominated the lake.
Structure of diatom flora in relation to water quality

The ACP analysis carried out with 6 environmental variables and 7 diatom dominant genera, highlighted the links between the environmental characteristics of the Ain Dalia dam and the different diatom dominant genera. Based on the two-first axes of the ACP, representing 72.21% of the variance, this analysis revealed that the phosphate, nitrite, pH, dissolved oxygen, temperature, and suspended matter significantly explained the variability diatom communities.

The first axis (43% of the variance) opposes nitrates, orthophosphates, and Nitzschia to dissolved oxygen and pH. This axis shows a clear difference between the group consisting of two stations St2 and St4, which is characterized by fairly high levels of nitrate, and orthophosphates as well the density of genus Nitzschia; and the group consisting of two other stations St1 and St3, which are richly oxygenated with high values of pH.

PCA axis II explains 29.20% of the total variability; it correlates positively with temperature and negatively with suspended solids. This axis shows a fairly clear temporal structure that allows us to form two groups: one including summer, autumn, and spring, which show relatively high temperature and relatively low suspended solids concentrations, and the other including only winter, when temperatures are low and suspended solids concentrations are high.

According to Kelly (2003), the distribution of diatoms is mainly explained by phosphorus; nutrients, primarily nitrogen and phosphorus, constitute one of the most important factors affecting the structure of the diatoms communities. Nehar (2016) has reported that distribution of diatoms in the aquatic environment is influenced by several biotic and abiotic factors, including substrate, pH, temperature and speed of water, chatter, pollution by organic and mineral matters. Likewise, El-Haouati (2015) has evidenced the links between the environmental characteristics of Reghaia Lake and the different diatom species. Moreover, Chaïb et al. (2011) and Chaïb and Tison-Rosebery (2012) have found a correlation between the environmental factors and the diatomic species through using Canonical correspondence analysis (CCA) and co-inertia analysis (CIA).

The results of the study show that (i) the diatom flora includes 72 species, the maximum richness was observed in summer and autumn (57 and 56 species respectively) and in station St4 (52 species); (ii) more than 40% of the overall density is encountered in station St4 and the fall period; (iii) Among the dominant genera, Cyclotella, Thalassiosira, Synedra and Navicula frequent moderately polluted waters and Nitzschia, Melosira and Surirella significantly polluted waters. (iv) The waters of the Ain Dalia dam are moderately (St1 and St3) to significantly polluted (St2 and St4), this provides lower quality habitats for the development and survival of diatoms. These microorganisms play a very important role for the biomonitoring of aquatic ecosystems as a bio-indicator of water quality. The need to protect these habitats from pollution and destruction is urgent. It is important to highlight the direct influence of nutrients (NO3 and PO43-), SM, temperature, and dissolved oxygen in the distribution of diatoms.
